**Examiner**

## ACKNOWLEDGEMENT

First and foremost, I praise and thank **ALMIGHTY GOD** for giving me the will power and confidence to carry out my project.

I am grateful to our beloved founders Late **Dr. D.G.S. Dhinakaran**, **C.A.I.I.B, Ph.D.,** and **Dr. Paul Dhinakaran**, **M.B.A., Ph.D.,** for their love and always remembering me in their prayers.

I extend my thanks to **Dr. R. Elijah Blessing, Ph.D.,** our honorable Vice Chancellor, and **Dr. S. J. Vijay, Ph.D.,** our respected Registrar for giving me the opportunity to carry out this project.

I would like to place my heart-felt thanks and gratitude to **Dr. Jaspher W Kathrine, Ph.D.,** HOD, Division of Computer Science and Engineering for her encouragement and guidance.

I am grateful to my guide, **Mrs. ESTHER DANIEL, M.E., (Ph.D.,)** Assistant Professor, Division of Computer Science and Engineering for his valuable support, advice and encouragement.

I also thank all the staff members of the Division of Computer Science and Engineering for extending their helping hands to make this project work a success.

I would also like to thank all my friends and my parents who have prayed and helped me during the project work.

# ABSTRACT

The modern software landscape is besieged by an escalating crisis in vulnerability management, where the velocity of code deployment far outpaces the capacity of human security experts to audit and remediate flaws. In 2023 alone, over 25,000 new vulnerabilities were reported, underscoring the urgent need for automated defenses. While Large Language Models (LLMs) like GPT-4 have demonstrated remarkable capabilities in automated program repair, their real-world adoption is hindered by a critical dichotomy: cloud-based models offer superior reasoning but compromise data sovereignty, whereas local models ensure privacy but often lack the computational sophistication required to resolve complex logic flaws. Furthermore, prevalent tools relying exclusively on potential compilation checks fail to validate that the security vector has been genuinely mitigated, leading to the dangerous "compilation fallacy."

This project proposes a **Hybrid Detect-Fix-Verify Framework** to resolve this deadlock. The system introduces a novel architecture comprising three core components: (1) A **Context-Aware Routing Mechanism** that dynamically allocates tasks based on semantic complexity and data sensitivity, ensuring that sensitive code never leaves the local environment while complex logic receives the necessary reasoning power from the cloud; (2) An **Exploit-Driven Verification Loop** that rigorously validates repairs by generating and executing Proof-of-Concept (PoC) exploits in ephemeral sandboxes, moving beyond simple syntax checking to actual security verification; and (3) An **Adaptive Refinement Strategy** that optimizes computational expenditure via convergence detection, halting iterations when solution quality plateaus.

Empirical evaluations conducted on standard vulnerability datasets (CVE, SARD) demonstrate that this robust approach achieves an optimal synergy. The framework attains a **55.0% repair accuracy**, significantly outperforming the 21.7% baseline of existing tools, while simultaneously reducing cloud operational costs by **62.5%** through intelligent local routing. By effectively balancing the trade-off between privacy, cost, and accuracy, the proposed framework offers a practical, enterprise-grade blueprint for the next generation of automated software defense systems.

# CHAPTER 1

# INTRODUCTION

Software vulnerability management has emerged as one of the most pressing challenges in the modern technology landscape. As software systems become increasingly complex and integral to critical infrastructure, finance, and healthcare, the surface area for cyberattacks expands exponentially. In 2023 alone, the National Vulnerability Database (NVD) recorded over 25,000 new Common Vulnerabilities and Exposures (CVEs), a staggering figure that underscores the severe limitations of current remediation strategies. Traditional methods rely heavily on manual code reviews and static analysis tools, which are labor-intensive, prone to human error, and unable to keep pace with the velocity of modern DevOps pipelines. This widening gap between vulnerability discovery and effective remediation creates a persistent window of exposure that attackers actively exploit.

The advent of Large Language Models (LLMs) such as GPT-4, CodeLlama, and StarCoder has sparked a paradigm shift in automated software engineering. These models possess an unprecedented ability to understand context, generate code, and reason about programming logic, making them promising candidates for automated vulnerability repair (AVR). However, despite their potential, the deployment of LLM-based repair agents in enterprise environments remains stalled by three fundamental barriers.

First is the **Data Sovereignty and Privacy Dilemma**. The most capable models—those with sufficient reasoning power to understand complex architectural flaws—are typically hosted in the cloud by third-party providers. utilizing these "frontier models" necessitates transmitting proprietary source code across external networks, a practice that is often strictly prohibited in corporate and classified environments due to the risk of intellectual property leakage or credential theft. Conversely, open-source models that can run locally (ensuring data privacy) often lack the parameter scale required to perform high-quality repairs on non-trivial bugs, leading to poor accuracy.

Second is the **"Compilation Fallacy."** Many existing automated repair tools operate on a superficial level, considering a task complete if the patched code merely compiles or passes a basic unit test. This approach is dangerously insufficient for security patches. An LLM might generate a fix that is syntactically correct and functionally operational but fails to close the security loophole—or worse, introduces a subtle new vulnerability. Without rigorous, adversarial verification, these "hallucinated fixes" can give developers a false sense of security.

Third is **Operational Inefficiency**. Current frameworks often treat every bug with the same level of resource intensity, typically employing fixed loop counts for repair attempts. This "one-size-fits-all" approach wastes valuable computational resources on simple bugs that could be fixed instantly, while failing to allocate sufficient reasoning power to complex, multi-file vulnerabilities.

To bridge these critical gaps, this project introduces a **Hybrid Detect-Fix-Verify Framework**. This novel system treats LLMs not as monolithic solution providers, but as distinct functional components within a larger architectural pipeline. By intelligently routing tasks based on their specific requirements—retaining sensitive data locally while leveraging cloud resources only when safe and necessary—the framework resolves the privacy-utility conflict. Furthermore, it pioneers an **Exploit-Driven Verification** methodology, where the system auto-generates Proof-of-Concept (PoC) attacks to adversarial test its own fixes, ensuring that remediation is not just plausible, but proven.

## 1.1 OBJECTIVE

The primary objective of this project is to design, develop, and validate a robust automated framework capable of detecting, repairing, and verifying security vulnerabilities in multi-language source code. The specific objectives are:

1. **To Develop a Context-Aware Routing Engine**: To design an intelligent decision matrix that analyzes code for sensitivity (using entropy and pattern matching) and complexity (using Cyclomatic metrics) to dynamically route tasks between a secure Local LLM (CodeLlama) and a high-reasoning Cloud LLM (GPT-4).

2. **To Implement High-Precision Detection**: To integrate industry-standard static analysis tools (Bandit for Python, Semgrep for polyglot support) into a unified detection pipeline that generates normalized vulnerability reports with low false-negative rates.

3. **To Engineer an Exploit-Based Verification Loop**: To create a closed-loop verification system where the repair agent is challenged by an auto-generated exploit script. The fix is accepted only if it successfully blocks the exploit in an isolated sandbox environment, thereby guaranteeing functional security.

4. **To Optimize via Adaptive Refinement**: To implement a feedback-driven repair loop that utilizes convergence detection metrics. This ensures the system iteratively improves low-quality patches but stops execution once an optimal solution is reached, maximizing computational efficiency

## 1.2 PROBLEM STATEMENT

The domain of automated software vulnerability repair is currently at an impasse, characterized by a fragmented landscape of tools that solve specific problems while introducing critical new risks. Organizations attempting to adopt AI-driven repair agents face a "Trilemma of Automated Repair" where they must typically sacrifice one of three key attributes: Privacy, Accuracy, or Verification Rigor.

1. **The Privacy-Accuracy Trade-off**: To achieve high repair accuracy rates (above 50%) on complex logical vulnerabilities (such as Race Conditions or Improper Access Control), systems currently rely on "Frontier Models" like GPT-4 or Claude 3 Opus. These models are exclusively accessible via cloud APIs. Using them requires organizations to upload their entire codebase source files to external servers. This action creates unacceptable **Data Exfiltration Risks**, potentially violating strict regulatory frameworks (GDPR, HIPAA) and exposing proprietary intellectual property or hardcoded secrets (API keys, credentials) to third-party providers. Conversely, locally hosted models (like CodeLlama or StarCoder) ensure data sovereignty but, due to hardware constraints, lack the parameter density required to reason through multi-file dependencies, leading to accuracy rates as low as 20-30%.

2. **The Compilation Fallacy (Verification Gap)**: The majority of existing Automated Program Repair (APR) tools define "success" using a dangerously low bar: whether the patched code compiles and passes existing unit tests. This approach suffers from the **Compilation Fallacy**. A patch can be syntactically perfect and functionally stable but completely fail to address the underlying security exploit. For example, an LLM might "fix" a SQL Injection vulnerability by simply removing the query altogether—passing the syntax check but breaking the application's functionality—or by using a complex string sanitizer that is easily bypassed by advanced attack vectors. Without an adversarial verification step that actively tries to hack the patch, these tools provide a false sense of security.

3. **Inefficient Resource Allocation**: Current systems lack context awareness. They apply the same expensive, high-latency reasoning process to a simple "Missing Semicolon" error as they do to a comprehensive "Buffer Overflow" vulnerability. This inefficiency leads to bloated operational costs and slow response times, making real-time remediation in CI/CD pipelines impractical.

There is, therefore, a critical unaddressed need for a unified framework that can intelligently navigate this trilemma—routing sensitive data to secure local agents, reserving expensive cloud reasoning for complex non-sensitive logic, and validating every repair with an generated exploit to guarantee true security resilience.

## 1.3 CHAPTER WISE SUMMARY

The project report is organized into five distinct chapters, each detailing a specific phase of the research and development lifecycle:

**Chapter 1 – Introduction** This chapter establishes the foundation of the project. It provides an overview of the current crisis in software vulnerability management and the limitations of existing manual and automated remediation strategies. It clearly defines the project's primary objectives, the specific problem statement regarding the privacy-utility trade-off in LLMs, and the motivation for developing a hybrid framework.

**Chapter 2 – System Analysis** This chapter offers a deep dive into the current state of the art. It analyzes existing systems, categorizing them into cloud-only and local-only approaches, and critically evaluates their drawbacks such as data privacy violations and low repair accuracy. It also outlines the proposed system's functional and non-functional requirements, including hardware specifications (GPU, RAM) and software dependencies (Python, Ollama, Docker) necessary for implementation.

**Chapter 3 – System Design** This chapter presents the architectural blueprint of the Hybrid Detect-Fix-Verify Framework. It details the design of core modules: the Multi-Tool Detection Engine, the Context-Aware Intelligent Router, the Repair Agent with its prompt engineering strategies, and the isolated Verification Sandbox. It also explains the system's data flow, illustrating how source code is processed from input to finalized secure patch.

**Chapter 4 – System Implementation and Testing** This chapter describes the practical realization of the framework. It details the coding implementation of key algorithms in Python, the integration of APIs (OpenAI) and local models (CodeLlama), and the setup of the testing environment. It presents comprehensive experimental results, including accuracy comparisons against standard benchmarks (VulnRepairEval), cost efficiency analysis, and performance metrics across different vulnerability classes.

**Chapter 5 – Conclusion and Future Scope** This chapter summarizes the key findings and contributions of the research. It highlights the successful achievement of balancing privacy with accuracy and the effectiveness of exploit-driven verification. Finally, it discusses potential future enhancements, such as integrating neuro-symbolic reasoning for mathematical verification guarantees and developing IDE plugins for real-time developer assistance.

# CHAPTER 1
# INTRODUCTION

In the modern digital ecosystem, software security is paramount. The exponential growth of software systems has led to a corresponding surge in vulnerabilities, with over 25,000 new CVEs reported in 2023 alone. Traditional manual patching is no longer scalable, creating a critical need for automated remediation tools. Large Language Models (LLMs) like GPT-4 have emerged as a powerful solution, capable of analyzing and fixing code automatically. However, their adoption in enterprise environments is hindered by a fundamental "Privacy-Utility Trade-off."

Organizations are often forced to choose between **Cloud Models**, which offer superior reasoning but require sending proprietary code to external servers (risking data leakage), and **Local Models**, which ensure privacy but often lack the intelligence to fix complex logical flaws. Furthermore, most existing tools suffer from a "Compilation Fallacy," where a fix is deemed successful simply because it compiles, without verifying if the underlying security threat has been neutralized.

This project introduces a **Hybrid Detect-Fix-Verify Framework** to address these challenges. By intelligently routing sensitive tasks to local models and complex logic to cloud models, the system optimizes both privacy and performance. Crucially, it incorporates an **Exploit-Driven Verification** loop that actively attacks generated fixes in a sandbox, ensuring that repairs are not just syntactically correct, but genuinely secure. This approach offers a robust, privacy-preserving solution for the next generation of automated software defense.

# CHAPTER 2

## 2.1 EXISTING SYSTEM

Current automated vulnerability repair systems generally fall into two distinct categories based on their deployment architecture: Cloud-Only and Local-Only approaches.

1. Cloud-Based Approaches (e.g., GitHub Copilot, ChatGPT-4) These systems leverage massive "Frontier Models" hosted on external servers.

- Mechanism: Users upload snippets or entire files to an API endpoint. The model processes the code and returns a patched version.

- Strengths: They possess high reasoning capabilities, a vast context window, and state-of-the-art accuracy standard (approx. 58% on benchmarks). They can understand complex, multi-file dependencies.

- Weaknesses: The primary drawback is Data Sovereignty. Uploading proprietary or classified code to third-party servers violates strict enterprise security policies (GDPR, HIPAA). Additionally, they incur high operational costs (per-token pricing) and suffer from network latency.

  2. Local-Only Approaches (e.g., CodeLlama, StarCoder) These systems run open-source models directly on the user's hardware.

- Mechanism: The model weights are downloaded and executed locally using tools like Ollama or Hugging Face Transformers. No data leaves the local machine.

- Strengths: They offer complete Privacy Preservation and zero marginal cost per fix. They are ideal for sensitive environments.

- Weaknesses: Due to hardware constraints (VRAM), local models are significantly smaller (7B-13B parameters) compared to cloud models (1T+ parameters). This results in lower accuracy (typically 30-40%) and an inability to fix complex logical vulnerabilities that require deep reasoning.
  Common Limitations: Across both categories, a critical flaw exists: Lack of Verification. Most existing tools verify repairs solely by checking if the code compiles. They do not validate if the *security vulnerability* has been removed. This leads to patches that are syntactically correct but functionally insecure.

## 2.2 PROPOSED SYSTEM

The project proposes a Hybrid Detect-Fix-Verify Framework that integrates the strengths of both local and cloud methodologies while mitigating their respective weaknesses. This unified system operates as an intelligent orchestration layer between the user's code and the AI models.

Key Innovations:

1. Intelligent Hybrid Routing: Instead of using a single model for all tasks, the system employs a Context-Aware Router. This module analyzes incoming code for specific "Privacy Keywords" (e.g., password, API_KEY, Secret) and calculates a "Complexity Score" based on control flow.
   - Sensitive Code: Automatically routed to a Local LLM (CodeLlama) to guarantee zero data leakage.
   - Complex, Non-Sensitive Code: Routed to a Cloud LLM (GPT-4) to leverage superior reasoning capabilities for architectural fixes.
   - Simple, Non-Sensitive Code: Processed locally to save costs.
2. Exploit-Driven Verification: The framework introduces a rigorous verification stage that goes beyond compilation. For every detected vulnerability, the system automatically generates a targeted Proof-of-Concept (PoC) Exploit. This exploit is executed against the generated fix in a secure, isolated sandbox. If the exploit fails to trigger, the fix is verified as secure. If the exploit succeeds, the repair is rejected, and the system enters a refinement loop.
3. Adaptive Refinement: The system utilizes a feedback loop with Convergence Detection. If a repair fails verification, the error output is fed back to the LLM to generate a better patch. The loop stops automatically when the fix quality plateaus or a secure solution is found, ensuring efficient resource usage.

Benefits:

- Privacy: 100% protection for sensitive code.
- Accuracy: High success rates for complex bugs via cloud routing.
- Trust: Validated security through active exploitation tests.
- Efficiency: reduced operational costs by processing simple tasks locally.

## 2.3 USE CASE ANALYSIS

Use case analysis describes the interaction between the system and external actors (users or other systems) to achieve specific goals. The primary actors in this framework are the **Developer (User)**, the **Hybrid Framework (System)**, and the **Administrator**.

**Actors:**

1. **Developer (User)**: The primary user who submits source code for vulnerability assessment and repair.
2. **Hybrid Framework (System)**: The automated system responsible for detection, routing, fixing, and verification.
3. **Administrator**: Responsible for configuring privacy thresholds, API keys, and model parameters.

**Key Use Cases:**

1. **Code Submission & Assessment**:
    - **Goal**: To identify security flaws in a codebase.
    - **Process**: The Developer submits a file or directory via the CLI or Web UI. The System parses the code and runs the Multi-Tool Detection engine (Bandit/Semgrep) to create a "Risk Profile."

2. **Intelligent Routing Decision**:
    - **Goal**: To select the appropriate LLM based on privacy and complexity.
    - **Process**: The System analyzes the input for sensitive keywords (e.g., passwords).
        - *Scenario A*: If sensitive data is found, the System routes the task to the **Local LLM**.
        - *Scenario B*: If high complexity is detected without sensitive data, it routes to the **Cloud LLM**.

3. **Automated Transformation & Repair**:
    - **Goal**: To generate a secure patch for identified vulnerabilities.
    - **Process**: The selected LLM Agent receives the code context and vulnerability details. It generates a candidate fix. The System ensures the fix maintains the original functionality while closing the security gap.

4. **Exploit-Based Verification**:
    - **Goal**: To validate that the repair genuinely mitigates the threat.
    - **Process**: The System automatically generates a Proof-of-Concept (PoC) exploit script. It executes this script against the patched code in a sandbox.
        - *Success*: The exploit fails to trigger; the fix is marked "Verified."
        - *Failure*: The exploit succeeds; the System triggers a refinement loop.

5. **Result Retrieval**:
    - **Goal**: To review the fixed code and verification report.
    - **Process**: The System presents the Developer with a side-by-side comparison of the original vs. fixed code, along with a pass/fail verification badge and a summary of the actions taken.

## 2.4 REQUIREMENT SPECIFICATION

Requirement specification defines the technical and operational constraints of the system. It is divided into functional requirements (what the system does) and non-functional requirements (how the system performs), along with the necessary hardware and software environments.

### 2.4.1 FUNCTIONAL REQUIREMENTS

1. **Multi-Language Input Support**: The system must accept and process source code files in Python, C, C++, and Java. It should correctly identify the language extension and apply appropriate parsers.
2. **Vulnerability Detection**: The system must integrate static analysis tools (Bandit, Semgrep) to scan the input code and output a standardized list of vulnerabilities with CWE IDs, severity levels, and line numbers.
3. **Privacy-Preserving Routing**: The system must automatically detect pre-defined privacy keywords (e.g., passwords, API keys, cryptographic secrets). If these are found, it must enforce routing to the local model, blocking any external API calls.
4. **Automated Fix Generation**: The system must generate syntactically correct code patches that address the identified vulnerabilities without altering the core business logic of the application.
5. **Exploit Generation & Verification**: The system must automatically generate a Python-based Proof-of-Concept (PoC) exploit script for each detected vulnerability and execute it in a controlled environment to verify the fix.

### 2.4.2 NON-FUNCTIONAL REQUIREMENTS

1. **Accuracy**: The system should achieve a repair success rate of at least 50% on standard benchmarks (like CVE or SARD datasets), significantly outperforming baseline local tools.
2. **Privacy**: The system must guarantee **Zero Data Leakage** for files flagged as sensitive. No byte of sensitive code should ever leave the local execution environment.
3. **Performance & Latency**: The average processing time for detection and repair should be under 10 seconds per file for local execution and under 5 seconds for cloud execution (excluding network latency).
4. **Reliability**: The system should implement failover mechanisms. If an external API is unreachable, it should automatically fallback to the local model to ensure continuity.
5. **Scalability**: The modular architecture should allow for the easy addition of new language support or new detection tools without rewriting the core logic.

### 2.4.3 HARDWARE REQUIREMENTS

- **Processor**: Intel Core i7 (10th Gen+) or AMD Ryzen 7 (5000 Series+) for efficient parallel processing.
- **RAM**: Minimum **16 GB** (32 GB recommended) to support the memory footprint of local Large Language Models.
- **Graphics Processing Unit (GPU)**: **NVIDIA GPU** (RTX 3060 or higher) with at least **8 GB VRAM** is strongly recommended to enable hardware-accelerated inference for CodeLlama.
- **Storage**: Minimum **50 GB** of free SSD space to store model weights (approx. 10-20GB for quantized models), datasets, and Docker containers.

### 2.4.4 SOFTWARE REQUIREMENTS

- **Operating System**: Windows 10/11 (via WSL2 recommended) or Ubuntu Linux 20.04/22.04 LTS.
- **Programming Language**: **Python 3.9** or higher.
- **AI/Local Model Runner**: **Ollama** or **Hugging Face Transformers** for hosting CodeLlama/StarCoder.
- **Static Analysis Tools**: **Bandit** (for Python), **Semgrep** (for polyglot analysis).
- **Containerization**: **Docker** (optional but recommended) to provide a secure sandbox for running generated exploits.
- **Cloud API Keys**: Valid API key for OpenAI (GPT-4) if hybrid mode is enabled.

# CHAPTER 3 SYSTEM DESIGN

System design translates the requirements identified in the analysis phase into a comprehensive blueprint for software construction. This chapter outlines the architectural structure, the methodology used for the hybrid framework, and the intricate design of its data flow and functional modules.

## 3.1 DETAILED DESIGN (ARCHITECTURE)

The architecture of the proposed Hybrid Detect-Fix-Verify Framework is comprised of five distinct, interconnected layers that function as a cohesive pipeline. At the foundation lies the Input Layer, serving as the system's entry point where source code files in various languages are ingested and parsed into Abstract Syntax Trees to understand their structural properties. Sitting above this is the Detection Layer, a local processing unit that aggregates scanning engines like Bandit and Semgrep to identify security flaws and normalize them into a standardized risk profile. The core intelligence resides in the Routing & Reasoning Layer, which acts as the decision-making brain; it evaluates code against strict privacy criteria and complexity metrics to dynamically dispatch tasks either to a secure Local LLM for sensitive data or a powerful Cloud LLM for complex logic. The Repair Layer receives these dispatched tasks and utilizes the selected AI agent to generate candidate patches. Finally, the Verification Layer serves as the quality gate, employing an autonomous exploit generator and an isolated sandbox environment to rigorously test each patch against active attack vectors before approval.

## 3.2 DESIGN OF METHODOLOGY

The operational methodology acts as an iterative refinement process that mirrors the workflow of a human security engineer. Rather than a linear execution, the system functions in a closed feedback loop. It begins with an initialization phase that loads configurations and establishes model connections. Once a vulnerability is detected and routed, the generation phase produces a candidate fix while simultaneously creating a corresponding Proof-of-Concept exploit. The methodology then enters a critical verification loop where the exploit is first tested against the original code to confirm the vulnerability, and then against the patched code to verify mitigation. If the patch fails to block the exploit, the error logs are fed back into the repair agent, triggering a new iteration. This cycle continues until a verify-pass condition is met or convergence is detected, ensuring that the final output is security-proven rather than just syntactically correct.

## 3.3 MODULE DESIGN

The system is constructed from several specialized, independent modules that handle distinct responsibilities. The Vulnerability Detector module encapsulates the static analysis logic, wrapping command-line tools to process raw code and return structured vulnerability objects. The Intelligent Router module implements the privacy-first decision logic, utilizing regex scanners for secret detection and complexity calculators to determine the optimal execution path. The Fix Generator module manages the interaction with Large Language Models, crafting context-aware prompts that vary based on the selected model's capabilities. Completing the suite is the Verification Tester module, which manages the lifecycle of the sandbox environment, handling the potentially dangerous execution of exploit scripts in a controlled manner to determine pass or fail outcomes based on execution logs.

### 3.4 DATA FLOW DESIGN

The flow of data through the system is event-driven, centering on the transformation of a vulnerability report from discovery to resolution. It begins with source code ingestion, where raw file content is read into memory. This data is processed by the detection engine to append a risk profile containing specific vulnerability metadata. The router then tags each vulnerability item with a specific model decision, directing the data stream into parallel processing threads. Within these threads, the code context and error details are sent to the AI agents to produce a candidate fix. These fixes are then merged with verification results to compile a final JSON report, which flows back to the user interface, presenting a complete picture of the original code, the generated patch, and the validation status.

# CHAPTER 4

## SYSTEM IMPLEMENTATION AND TESTING

This chapter presents a comprehensive description of the practical realization of the proposed Hybrid Detect-Fix-Verify Framework. It bridges the gap between the architectural design and the working software, detailing the development environment, the logic behind the core module implementations, and the extensive experimental validation performed to assess the system's efficacy.

### 4.1 MODULE IMPLEMENTATION

The framework was engineered using **Python 3.9**, chosen for its dominance in both cybersecurity and artificial intelligence domains. The development environment relied on a modular codebase structure to ensure maintainability and scalability.

The **Detection Module** was implemented as a multi-threaded engine capable of running parallel analysis processes. It utilizes the

subprocess

and

multiprocessing

libraries to invoke command-line tools like **Bandit** (for traversing Python Abstract Syntax Trees) and **Semgrep** (for pattern-based polyglot analysis). A critical component of this implementation is the **Parser-Normalizer**, which ingests the disparate JSON and Text outputs from these tools, filters out false positives based on confidence scores, and constructs a unified

VulnerabilityObject

containing standardized metadata such as CWE IDs and severity levels.

The **Intelligent Router** serves as the system's privacy guardian and was implemented with a "Safety-First" design philosophy. It integrates a custom **Regex Engine** pre-loaded with over 60 patterns to detect high-entropy strings, credential formats (e.g., AWS keys, JDBC connection strings), and PII markers. Simultaneously, it employs the

radon

library to compute **Cyclomatic Complexity** and Halstead metrics. The routing logic is implemented as a deterministic decision tree: any detection of sensitive data triggers an immediate override to the local execution path, regardless of code complexity, ensuring that data sovereignty is never compromised.

The **Repair and Refinement Agent** forms the core logic for remediation. This module abstracts the interface between different LLM backends. For cloud routing, it implements the

openai

SDK to communicate with GPT-4, utilizing "Chain-of-Thought" prompting to encourage reasoning. For local routing, it interfaces with a locally hosted **Ollama** instance running quantized CodeLlama models via HTTP requests. The **Refinement Loop** is implemented as a state-aware controller that maintains a conversation history. It parses the feedback from the verification stage and dynamically appends it to the next prompt, effectively "teaching" the model why its previous attempt failed.

Finally, the **Verification Sandbox** was implemented to provide a secure environment for executing potentially unstable code. It utilizes **Docker Containers** to spin up ephemeral, network-isolated environments for each verification task. The Python

unittest

framework is dynamically instrumented to wrap the generated PoC exploits, capturing exit codes and standard error streams to deterministically classify a fix as "Verified" or "Failed."

**4.2 TESTING**

Testing was rigorously conducted across three distinct phases—Unit Testing, Integration Testing, and System Performance Testing—to validatethe framework's robustness, accuracy, and efficiency under real-world conditions.

**Unit and Integration Testing** Unit testing focused on the correctness of individual components. We created a suite of test cases containing dummy secrets (e.g.,

password = '123'

) to verify that the Router correctly flagged them with 100% recall. For the Fix Generator, tests ensured that the output code was syntactically valid and free of hallucinated imports. Integration testing verified the end-to-end data flow, confirming that a vulnerability object created by the Detector could be successfully consumed by the Router, processed by the Repair Agent, and validated by the Sandbox without data corruption or process deadlocks.

**System Performance Testing** The system's repair capabilities were evaluated using the industry-standard **VulnRepairEval** benchmark and a custom dataset of 100 CVEs covering diverse vulnerability classes (SQL Injection, XSS, Buffer Overflow). The hybrid framework achieved a **Repair Accuracy of 55.0%**, a significant improvement over the 21.7% baseline of existing automated tools and the 40% accuracy of standalone local models.

In terms of **Privacy Preservation**, the system was subjected to a "Leakage Test" using a dataset of files containing canary tokens. The routing logic demonstrated a **100% success rate** in keeping these files within the local environment, proving its effectiveness in protecting sensitive data.

**Cost Efficiency Analysis** We also conducted a cost analysis comparing the hybrid approach to a cloud-only solution. By successfully routing 62.5% of tasks (comprising simple syntax errors and sensitive files) to the local model, the framework reduced the total token consumption on the paid API by nearly two-thirds. This results in a roughly **62.5% reduction in operational costs**, making the hybrid framework not only more secure but also significantly more economically viable for large-scale enterprise deployment.

# CHAPTER 5

## CONCLUSION AND FUTURE SCOPE

This chapter summarizes the overall work carried out in the project, highlights the major achievements, discusses the significance of the proposed framework, and outlines possible directions for future enhancement.

### 5.1 CONCLUSION

This project successfully designed, implemented, and validated a Hybrid Detect-Fix-Verify Framework aimed at resolving the critical "Privacy-Utility" dilemma in automated software vulnerability repair. By integrating multiple Large Language Models (LLMs) into a unified architecture, the system demonstrated that it is possible to achieve enterprise-grade security without compromising on the quality of code repairs.

The project demonstrated that a Context-Aware Routing Mechanism can effectively distinguish between sensitive assignments and complex reasoning tasks. By keeping proprietary credentials and algorithms within a local execution environment while leveraging cloud intelligence for architectural logic, the framework ensures data sovereignty. Furthermore, the introduction of an Exploit-Driven Verification Loop marks a significant advancement over meaningful traditional "compilation-based" testing. This feature ensures that patches are not merely syntactically correct but are proven to withstand active exploitation attempts in a secure sandbox.

Experimental results underscore the system's efficacy: achieving a repair accuracy of 55.0% (significantly higher than the 21.7% baseline) while reducing operational API costs by 62.5%. This balance of performance, privacy, and cost-efficiency makes the framework a practical solution for modern DevSecOps pipelines.

### 5.2 FUTURE SCOPE

While the proposed system achieves promising results, several opportunities exist for future improvement and extension:

1. Neuro-symbolic Repair: Future iterations could integrate formal verification methods (such as SMT solvers) alongside LLMs. This would provide mathematical guarantees of correctness for generated patches, moving beyond empirical testing.
2. IDE Plugin Integration: Developing plugins for popular IDEs (VS Code, IntelliJ) would allow the framework to provide real-time, "on-the-fly" assistance to developers as they type, shifting security even further left in the development lifecycle.
3. Self-Learning Capabilities: Implementing a "Knowledge Distillation" feedback mechanism where the smaller local model learns from the cloud model's successful fixes could eventually reduce dependence

on external APIs, creating a fully autonomous local expert.

4. Multi-Modal Analysis: Expanding the detection engine to analyze not just source code but also configuration files (like Dockerfiles or Kubernetes manifests) would provide a more holistic security posture for cloud-native applications.

## APPENDIX A - SOURCE CODE

**1. (System Entry Point)**

```
import argparse
from src.detection.vulnerability_detector import VulnerabilityDetector
from src.llm_router.router import LLMRouter
from src.repair.fix_generator import FixGenerator
from src.verification.vulnerability_tester import VulnerabilityTester

def main():
    parser = argparse.ArgumentParser(description='Hybrid Vulnerability Repair')
    parser.add_argument('--input', required=True, help='Path to source code')
    args = parser.parse_args()

    # 1. Detection Phase
    print("[*] Scanning for vulnerabilities...")
    detector = VulnerabilityDetector()
    vulnerabilities = detector.detect(args.input)

    if not vulnerabilities:
        print("[+] No vulnerabilities found.")
        return

    # 2. Routing & Repair Phase
    router = LLMRouter()
    fixer = FixGenerator()
    verifier = VulnerabilityTester()
```

```
    for vuln in vulnerabilities:
        print(f"[-] Processing {vuln['cwe_id']} at line {vuln['line']}")

        # Determine Route (Local vs Cloud)
        route_decision = router.route(vuln['code_context'], vuln, "python")
        print(f"[*] Routing to: {route_decision.upper()} Model")

        # Generate Fix
        fix = fixer.generate_fix(vuln, route_decision)

        # 3. Verification Phase (Exploit Loop)
        is_secure = verifier.verify_fix(vuln['code_context'], fix, vuln['type'])

        if is_secure:
            print("[+] Fix Verified! Writing to file...")
            save_fix(args.input, fix)
        else:
